Keywords:
River stage tomography
Hydraulic tomography (HT)
Hydraulic diffusivity (D)

ABSTRACT

The objective of this study is to demonstrate the ability of riverstage tomography to estimate 2-D spatial distribution of hydraulic diffusivity (D) of Zhuoshui River alluvial fan, Taiwan, using groundwater level data from 65 wells and stream stage data from 5 gauging stations. In order to accomplish this objective, wavelet analysis is first conducted to investigate the temporal characteristics of groundwater level, precipitation, and stream stage. The results of the analysis show that variations of groundwater level and stream stage are highly correlated over seasonal and annual periods while that between precipitation is less significant. Subsequently, spatial cross-correlation between seasonal variations of groundwater level and riverstage data is analyzed. It is found that the correlation contour map reflects the pattern of sediment distribution of the fan. This finding is further substantiated by the cross-correlation analysis using both noisy and noise-free groundwater and riverstage data of a synthetic aquifer, where aquifer heterogeneity is known exactly. The ability of riverstage tomography is then tested with these synthetic data sets to estimate D distribution. Finally, the riverstage tomography is applied to the alluvial fan. The results of the application reveal that the apex and southeast of the alluvial fan are regions with relatively high D and the D values gradually decrease toward the shoreline of the fan. In addition, D at northern alluvial fan is slightly larger than that at southern. These findings are consistent with the geologic evolution of this alluvial fan.

1. Introduction

For managing groundwater resources in a basin, information about hydraulic property distributions, which controls water and contaminant movement and their distributions in the basin, is essential. With this information, numerical surface water and groundwater models can be used for long-term management of water resources through estimation, prediction, and scenario analysis of surface water and groundwater systems.

Hydraulic tomography (HT) is a recently developed technique for characterizing subsurface heterogeneity. The rationale of HT is a joint interpretation of non-fully-redundant information about aquifer heterogeneity carried by drawdown fields induced from pumping tests at different locations. Specifically, successive pumping tests at different locations create different flow fields. Each flow field allows given observation wells to observe heterogeneity at certain parts of an aquifer at one perspective. Different flow fields thus facilitate viewing the heterogeneity at many different perspectives, using the same observation wells. HT can also include different types of information, such as observed head and flux (Zha et al., 2014; Tso et al., 2016), and prior geologic information such as layering (Tso et al., 2016; Zhao et al., 2016; Zhao and Illman, 2017). It has been successively applied to small-scale synthetic aquifers (Hao et al., 2008; Yeh and Liu, 2000; Zhu and Yeh, 2005, 2006), laboratory sandboxes (Illman et al., 2007; Liu et al.,...
2002, 2007), plot-scale fields (Berg and Illman, 2011, 2013, 2015; Bohling et al., 2007; Cardiff et al., 2012; Huang et al., 2011; Li et al., 2007a; Straface et al., 2007; Vesselinov et al., 2001), and fractured granite field sites (Illman et al., 2009; Zha et al., 2014, 2015). Its usefulness has been well documented by many studies.

HT relies on artificial excitations such as pumping or injection of water. However, it is difficult or impractical to apply HT to basin-scale aquifer characterization because of ineffectiveness of artificial hydraulic tests for altering groundwater flow fields over kilometers or basin scales. Natural stimuli, such as atmospheric pressure variations (Rojstaczer, 1988), solid earth tides (Hsieh et al., 1988; Rojstaczer and Riley, 1990), ocean tides (Davis et al., 2000; Li et al., 2007b), precipitation (Jan et al., 2013), and even earthquake (Lin et al., 2004), are found to induce groundwater fluctuation from local to regional flow systems. For these reasons, Yeh et al. (2008) proposed utilizing natural stimuli as excitation sources for basin-scale hydraulic tomographic surveys.

River-stage tomography is a concept of extracting subsurface heterogeneity information from groundwater variation induced by changes in the river water level and migration of the flood wave from the upper to downstream. The time scale of variations could be event, seasonal, or even annual basis. Yeh et al. (2008, 2009) explored this possibility of characterizing basin scale subsurface heterogeneity. They used a synthetic stream-aquifer system to demonstrate the potential of river-stage tomography utilizing event-based flood waves. Furthermore, recharge rates to groundwater aquifer from river through stream bed were simulated from Darcy’s flux and were utilized to represent the surface water-/groundwater exchange in the work of Yeh et al. (2009). This rate in the real world applications is unknown. Besides, groundwater level information recorded in a basin is likely influenced by many factors (such as precipitation, pumping, regional flow, and others). How to extract useful information from these data sets for characterizing basin-scale aquifer heterogeneity remains to be a challenge. For all these reasons, the applicability of the riverstage tomography for aquifer characterization in real world scenarios remains to be assessed.

While in this paper, interaction between surface water and groundwater is introduced by treating the river as a prescribed head boundary. This choice is due to the reason that the hydraulic conductivity (K) of the stream bed usually is not available in the field dataset. As a result, the objective of this paper is to estimate basin-scale D fields using stream induced groundwater level variations utilizing both synthetic and field data. In addition, the validity of treating the river as a prescribed head boundary on the hydraulic parameter estimation is discussed.

In order to achieve this goal, we first use wavelet analysis to analyze long-term precipitation, riverstage, and groundwater time series collected at the Zhuoshui River alluvial fan, Taiwan to select appropriate time span and data sets for spatial cross-correlation analysis. We compare the contour maps of the maximum cross-correlation and lag time between the riverstage and groundwater with the map of geology of the site to check the feasibility of the approach. We then use flow model to simulate groundwater level responses to the fluctuations of riverstage in a synthetic alluvial fan resembling the field site. The simulated groundwater responses and the riverstage information are then used to evaluate the performances of the cross-correlation and riverstage tomography analyses. The results from the noise-free and noise corrupted groundwater responses shed lights on the validity of those for the alluvial fan using field data, which may be influenced by many factors not considered. Afterward, the riverstage tomography is applied to estimate D spatial distribution at the Zhuoshui River alluvial fan and the results are discussed.

2. Site description

The ideal candidate for the application of the river-stage tomography would be a groundwater basin that has been well instrumented and monitored. That is, the basin must have a large number of observation wells at different locations with screens opened at different depths and a sufficient number of river gauging stations. Most importantly, long term and high frequency (at least hourly) records of groundwater levels, riverstage, precipitation, and other hydro-meteorological processes over the basin are required. Few basins in the world meet this requirement because of costs associated with the operations and maintenances. The Zhuoshui River alluvial fan in Taiwan is uniquely qualified for this purpose because of massive amount of hydro-geological data has been collected since 1992 primarily for the purpose of irrigation groundwater management and earthquake investigations.

2.1. Topography

The Zhuoshui River alluvial fan (Fig. 1a) is located at mid-west part of Taiwan. It is about 70 km long and 40 km wide and has an area of 1800 km². It is bounded by Wu River at the north, Beigang River at the south, Taiwan Strait at the west, and the Central Mountain Range at the east. The Zhuoshui River cuts through the mountain pass of the ridge between Bagua Plateau and Douliu Hill at the center of the fan, and flows from east to west through the middle part of the fan and discharges into Taiwan Strait. The elevation of the fan is about 100 m at the apex and 0 m at the tail. The elevation drops from 100 to 30 m within 10 km after exiting the mountain pass between Bagua Plateau and Douliu Hill. Groundwater level is generally 30 m below the ground surface at the upper fan and 10 m below the ground at middle and tail.

2.2. Geology

The Central Geological Survey (1994, 1999) constructed 12 hydro-geological profiles for the alluvial fan based on the core samples from drilled wells. An unconfined and three confined aquifers, namely, layer 1 to layer 4, were approximately identified from shallow to 300 meters depth. The geological investigation indicated that all of the aquifers are connected to each other at apex of the fan where the deposition is mainly gravel (blue zones in Fig. 1b). This alluvial fan consists of several layers of Holocene to Pleistocene sands and gravels, which form the three confined aquifers separated by marine mud (Central Geological Survey, 1994, 1999). It suggested that the rising and falling of the mean sea levels caused by global climate change late in the Quaternary Period created the layered structure of the alluvial fan (Water Resources Agency, 2014). Massive gravels and coarse sands, which comprise many layers of the upper fan, pinch out toward the west of the fan at shoreline, while the mud layers thicken. An interface between the gravels and the arenaceous sediments was identified that separates the partially confined and confined aquifers.

The distribution of sediments in the alluvial fan follows gravel, sand, and clay from the apex to the tail of the alluvial fan. This pattern agrees with the sedimentation process of the river that angular conglomerates and breccias tend to settle down at the headwater where transport energy is relatively high, while the arkose and finer materials such as silt and clay tend to be at the middle and tail of the river, which has low transport energy. Due to the drift of the flow path of Zhuoshui River in the past, the sediment profile at northern part of middle alluvial fan exhibits interlocked sand and silt/clay features. On the other hand, the southern part of the alluvial fan does not manifest such features. This is probably attributed to the fact that the sediment in the southern
part was deposited by Beigang River, instead of Zhuoshui River, and the source of the sediment was from Douliu Hill. The region at the northern boundary of the alluvial fan near the Wu River and west foot of Bagua Plateau mainly consists of gravels. (Water Resources Agency, 2014)

2.3. Hydrological data availability

A groundwater monitoring network system was gradually established throughout the fan since 1992 and was expanded to the current size at 1997. The network consists of 74 evenly distributed groundwater stations, where 188 monitoring wells are installed at various depths ranging from 24 through 306 m. Most of the wells are screened at only single depth, and the water levels at all of the wells have been recorded hourly since 1997. In this study, 65 monitoring wells are selected. All of them have screen intervals opened at the unconfined or partially confined aquifer. The partially confined aquifers mostly locate along the southern alluvial fan where mainly consists of silt/clay. Most screen intervals are opened at depth ranging from 8 to 103 m with screen

![Figure 1](image_url)

**Fig. 1.** (a) Locations of wells (black circles), precipitation stations (red triangles), and river gauging stations (green squares). The river gauging stations, from upstream to downstream, are Zhangyun Bridge, Xizhou Bridge, Ziqiang Bridge, and Xibin Bridge, respectively. The precipitation station located at apex of the fan is Xiashupu while the one below the scale is Chiayi station. The black circles with square are the groundwater monitoring wells 1 and 15 km away from the river, namely, Tan-Cian (1-1) and Si-Hu (1) stations, respectively. (b) The geological cross section along the solid black line in figure 1a. Blue, green, yellow, and orange zones in the cross section represent gravel, coarse sand, fine sand, and silt/clay, respectively. The labels B1, B2, and B3 in the geological cross section roughly indicate the bottom of each aquifer. c) Long term precipitation (mm/day) at Chiayi station, stream flow rate (m$^3$/s) at Ziqiang Bridge, and average groundwater level (m) during 2008 to 2014 (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.).
length between 6 to 18 m, while the others are from 50 to 300 m with screen length between 6 to 60 m. There are 21 stream gauges along the rivers through the fan. Stream stage or flow rate utilized in this study are labeled in Fig. 1a. There are four stream gauging stations (namely, Zhangyun Bridge, Xizhou Bridge, Ziqiang Bridge, and Xibin Bridge) along the Zhuoshui River, located at the apex, middle, and the tail of the alluvial fan, respectively. Stream gauge (Dadu Bridge) at downstream of Wu River at northern boundary of the alluvial is also used in this study. Riverstage and flow rate have been recorded hourly. In addition, hourly meteorological data has been collected from about 50 weather stations since 2009. We select Xiasiupu weather station located at apex of the fan for the precipitation analysis. Daily precipitation records since 1997 recorded at Chiayi weather station, which located 40 km southern from the Zhuoshui River are analyzed.

3. Methods of analyses

As mentioned previously, groundwater level fluctuations may reflect excitations from a large number of natural processes (precipitation, evapotranspiration, or earthquakes) or human activities (e.g., pumping and irrigation) at different time scales and frequencies, other than riverstage. To discriminate these various components in groundwater level signals is intractable because of the lack of data and knowledge of all processes. Instead, we use wavelet analysis to examine temporal variation of riverstage and groundwater data to select the most appropriate time where the relationships of the two are most significant. We then examine the spatial correlation between riverstage and groundwater data at different parts of the fan. Afterward, we use successive linear estimator (SLE) algorithm and the riverstage and groundwater data to estimate hydraulic diffusivity (D) distribution in the fan. This section briefly discusses the wavelet analysis, spatial cross-correlation analysis, and the SLE algorithm.

3.1. Wavelet analysis

Many methods for analyzing time series, including Fourier transform, cosine and sine transform, and orthogonal polynomial expansion are available. Unlike these methods, time-frequency analysis methods such as wavelet transform could derive the instantaneous frequency. Similar to the Fourier transform, the wavelet transform measures the similarity between signal and analyzing function by using their inner product

$$C(a, b) = \frac{1}{\sqrt{b}} \int_{-\infty}^{\infty} f(t) \psi \left( \frac{t-a}{b} \right) dt$$

where \(f(t)\) is the time series of riverstage or groundwater data and the analyzing function is a mother wavelet \(\psi(t)\). \([T]\) is time. The wavelet transform compares the signal with shifted and compressed or stretched the mother wavelet using location \(a\) \([T]\) and scaling \(b\) \([1/T]\) parameters. The resulting transform \(C(a, b)\) is a function of location and scaling parameters called wavelet coefficient or wavelet amplitude spectrum. The square of wavelet coefficient could be seen as power spectrum, which indicates the relative energy distribution along different location and scale.

Because the mother wavelet is not an infinite sinusoid function, there is only an approximate answer for the relationship between the scale \(b\) and frequency. In wavelet analysis, the way to relate the scale to frequency is to determine the center frequency \(f_c\) \((1/T)\) of the wavelet and use the following relationship

$$f(a) = \frac{f_c}{b\Delta}$$

where \(f(a)\) is the pseudo-frequency \([1/T]\) corresponding to the scaling parameter \(\Delta\) is the sampling period \([T]\). The center frequency \(f_c\) is the specific frequency that has the strongest amplitude or contributes the most energy to the construction of mother wavelet.

There are many mother wavelets such as Haar, Gaussian Morlet, Meyer, and Daubechies could be chosen (Misiti et al., 2007). The rationale behind choosing the proper mother wavelet is using those which could best describe the characteristics (i.e., the sharp or smooth transitions between peak and trough) of the signal to be analyzed. In practices, one could take a trial and error approach to test the reconstructing performance of different wavelets. The similarity between the reconstructed and original signal gives some hint on how the given wavelet is capable of representing the signal. Here, we choose Mexican hat function because it best describes the original signal. Mexican hat function is the 2nd order derivation of the Gaussian function.

$$\psi(t) = \frac{2^{1.5}}{\sqrt{3}} (1 - 2\pi t^2) \exp(-\pi t^2)$$

The inverse wavelet transform is defined as

$$f(t) = \frac{1}{C_p} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} C(a, b) \psi \left( \frac{t-a}{b} \right) dadb$$

$$C_p = \int_{-\infty}^{\infty} |\Psi(\omega)|^2 d\omega < \infty$$

where \(\Psi(\omega)\) is the Fourier transform of \(\psi(t)\), and \(\omega\) \([1/T]\) is frequency.

Wavelet coherence is a method identifying relationships between two signals in frequency as well as in time. Wavelet coherence is evaluated by magnitude-squared coherence, which is

$$\text{coh}(\omega, t) = \left[ \frac{\sum_{i=1}^{N} C_i(\omega) - \overline{C}(\omega, L) - \overline{H}(\omega, L)}{\sqrt{\sum_{i=1}^{N} C_i(\omega) - \overline{C}(\omega, L) - \overline{H}(\omega, L)}^2 \sum_{i=1}^{N} (H_i(\omega, L) - \overline{H}(\omega, L))^2} \right]$$

where \(C\) and \(H\) are wavelet coefficients of two signals, \(C\) and \(H\) are the average wavelet coefficients within the smoothing domain in time and frequency, \(N\) is total number of sampling within the smoothing domain, and \(L\) is time or phase lag. * denotes conjugate of the complex number. \(\text{coh}(\omega, t)\) could be any value ranging between 0 and 1 while 1 means the two signals at the certain time and frequency are perfectly correlated with certain lag of time and 0 means uncorrelated. Thus, it could be conceptualized as a localized correlation coefficient in the time and frequency domain. Notice that instead of Mexican hat, we utilize Morlet as the mother wavelet in the coherence analysis. The reason of choosing another mother wavelet is because the wavelet coefficient of Mexican hat does not have imaginary part while Morlet does. Without the imaginary part, the influence of phase lag (i.e., time lag) on the similarity among two signals could not be displayed. Here, we utilize MATLAB wcoherence function to conduct the coherence analysis.

3.2. Spatial cross-correlation analysis

After identifying the time periods where the groundwater level data are highly correlated with those of the riverstage, correlation between riverstage at different gauging stations and groundwater fluctuation at each individual well is investigated by cross-correlation analysis. The cross-correlation is an index providing the similarity of two time series as a function of time lag of one relative to the other. It is evaluated using the following formula:
and groundwater level, respectively.

\[ \text{Cor}(L) = \frac{\frac{1}{N} \sum_{i=1}^{N} (h(i) - \bar{h})(g(i + L) - \bar{g})}{\sqrt{\frac{1}{N} \sum_{i=1}^{N} (h(i) - \bar{h})^2 \frac{1}{N} \sum_{i=1}^{N} (g(i) - \bar{g})^2}} \]

where Cor(L) is the cross-correlation and L [T] is time lag or sampling point lag; h [L] and g [L] represent time series of stream stage and groundwater level, respectively. h and g are the means, and \( \sigma_h \) and \( \sigma_g \) are the standard deviations of the corresponding time series. They are obtained using entire Nth number of data. N is the total number of data in time series.

3.3. Successive linear estimator

The goal of this study is to demonstrate the feasibility to utilize the groundwater variation in response to the river stage change to characterize the hydraulic diffusivity of the alluvial fan. In order to accomplish this goal, a stochastic estimator (successive linear estimator, SLE, developed by Yeh and his colleague) is used. A brief description of the estimator is given below. Detailed discussion could be found at Yeh et al. (1996), Zhang and Yeh (1997) and Zhu and Yeh (2005).

Suppose we adopt a highly parameterized heterogeneous conceptual model for the fan and discretize the domain of the fan into \( n \) elements. Suppose we have collected a total number of \( m \) observed heads at wells in the fan in time and space, denoted by \( h^r \) (\( m \times 1 \)). The estimation of parameter fields, given the observed heads, is iteratively determined using the following linear estimator:

\[ \hat{f}^{r+1} = \hat{f}^r + \omega^r \left[ h^r - h^{r+1} \right] \]

Where \( \hat{f}^r \) is a \( n \times 1 \) vector, representing perturbations of the estimated \( \ln \)D (i.e., the estimates minus the unconditional mean \( \ln \)D), and the superscript \( r \) is the iteration index. \( h^{r+1} \) (\( m \times 1 \)) is the simulated heads at the observation wells, based on the \( \ln \)D estimated from previous iteration. If \( D \) measurements are not available, \( \hat{f}^{r+1} \) is zero and the estimated \( D \) is the unconditional mean \( D \). On the other hand, if some \( D \) measurements are available, one can use kriging to derive the conditional mean \( D \) field and \( \hat{f}^{r+1} \) is then the perturbation of kriging estimates about the unconditional mean \( D \) field.

In Eq. (7), the matrix \( \omega^r \) (\( n \times m \)) is the weight matrix, representing the contribution of the difference between the observed and simulated conditional heads (i.e., \( h^r \) and \( h^{r+1} \), respectively) to the improvements for the previous estimated \( \ln \)D. The matrix \( \omega^r \) is determined by solving the following equation:

\[ \omega^r = e^{r+1} \left( e^{r+1} \right)^T \]

The matrix \( e^{r+1} \) (\( m \times m \)) is the conditional covariance of observed head while the matrix \( e^{r+1} \) (\( n \times m \)) is the conditional cross covariance between head and each element. They are evaluated using the first-order approximation. That is,

\[ e^{r+1} = \left[ \begin{array}{c} e^{r+1}_{1m} \\ \vdots \\ e^{r+1}_{nm} \end{array} \right] \]

\[ e^{r+1}_{jm} = \int h_j^r \left( e^{r+1} \right)^T \]

where \( J^r_j \) (\( n \times m \)) is the sensitivity of head with respect to the change of parameter. The sensitivity matrix is evaluated using the adjoint state approach (Li and Yeh, 1998, 1999; Lu and Vesselinov, 2015). After completion of the linear estimation, the conditional residual covariance of \( f^{r+1} \) is updated subsequently by

\[ e^{r+1}_{jj} = e^{r}_{jj} - \omega^r e^{r}_{jm} \left( e^{r+1} \right)^T \]

These steps are repeated successively to improve the estimate of \( f^r \) for iteration \( r \geq 1 \).

When solving Eq. (8), a dynamic stabilizer is added into it for the purpose of numeric stability. Furthermore, the measurement error could be considered as well. That is, Eq. (8) is rewritten as

\[ \omega^r \left( e^{r+1}_{nm} + R + \theta^r d \right) = e^{r+1}_{m} \]

where \( R (m \times m) \) is the covariance matrix of the measurement error and \( \theta^r (1 \times 1) \) is the dynamic stabilizer. Dynamic stabilizer is added to the diagonal elements of \( e_n^r \) times a user-specified multiplier (Yeh et al., 1996) if the dimensions or orders of magnitude of observed data are identical. If the dimensions or orders of magnitude of observed data are different, then it is better to use the value of the diagonal elements of \( e_n^r \) times a user-specified multiplier as the dynamic stabilizer to insure the contribution from the small orders of magnitude observed data as well as the contribution from measurement with different dimensions (Zha et al., 2014).

At the beginning of the iteration, we need to specify the initial guessed values for the parameter field (\( f^0 \) used in Eq. (7)) and covariance function (\( e^{r+1}_{nm} \) used in Eqs. (9) and (10)). From the Bayesian perspective, it is reasonable to use the prior information, such as knowledge of mean and variance of the unknown parameter field, as initial guess. After that, the parameter field and the covariance will be updated iteratively due to gradual assimilation of observation information.

Two criteria, the mean absolute error (\( L_1 \) norm) and the mean squared error (\( L_2 \) norm) are used to evaluate the differences between observed head and simulated head:

\[ L_1 = \frac{1}{m} \sum_{i=1}^{m} \left| h_i - h^{(r)}_i \right| \text{ and } L_2 = \frac{1}{m} \sum_{i=1}^{m} \left( h_i - h^{(r)}_i \right)^2 \]

4. Analyses and results

4.1. Temporal analysis of head, riverstage, and rainfall data

4.1.1. Periodicity analysis

The daily time series and its associated wavelet spectrograms of groundwater levels at all available observation wells and river flow rate at Zhangyun Bridge during 1997–2013 are analyzed. It is observed that the groundwater level and river flow rate during 1997–2013 have significant periodic variations on annual period (Fig. 1c). The annual periodic cycle of the flow rate follows the meteorological characteristics of the area. That is, frequent precipitation during rainfall season from April to October leads to the increase in surface runoff and in turn, the stream discharge. The lack of rainfall during the winter and early spring leads to low flow rate of the river. The annual groundwater level variation, on the other hand, follows the trends of both agriculture water demand...
and meteorological characteristics. Generally, groundwater levels decrease at the first half portion of the growing season due to pumping and evapotranspiration, which begins from early spring until May, and afterward, the groundwater levels start to recover because of the rainfall season. The amount of recovery depends on recharge from rainfall and groundwater withdraw.

Two selected wells, Tan-Cian (1-1), Si-Hu (1) (labeled with square in Fig. 1a), located at about 1 and 15 km, respectively, away from the river are utilized to illustrate the relationship between the groundwater level variations within the alluvial fan and the riverstage as well as precipitation. The reasons for choosing these two wells are that Tan-Cian is the nearest well to the stream, while Si-Hu is located almost at the center of the northern alluvial fan.

Hourly water levels during 2010 are selected as the example to investigate the higher frequency signals. Fig. 2a–c illustrate the hourly time series and its associated wavelet spectrograms of groundwater level at Tan-Cian (1-1), Si-Hu (1), and stream stage at Ziqiang Bridge, respectively. It can be observed that as the distance between monitoring well and riverstage measurement location becomes further apart, the groundwater level hydrograph becomes smoother and oscillates less. The phenomenon that higher frequency groundwater level fluctuations are filtered by the aquifer is presented in wavelet spectrogram as well. Compared spectrograms between Tan-Cian (1-1) and Si-Hu (1), amplitude spectrums of high frequency signals at further well are less than the closer one.

In addition, during the rainfall season (i.e., April to October: 100 to 300 on the horizontal time axis), by taking a glance through these time series, it seems that there are some periodic groundwater level and stream stage peaks and troughs, although they are not obvious. On the other hand, the groundwater level and stream stage during the rest of the day are flat. To better explore the temporal periodic variations quantitatively, we relate the time series to wavelet spectrograms. It is observed in spectrograms at Tan-Cian (1-1) and Si-Hu (1) that there are some positive-negative (i.e., the warmer-cooler color) amplitude spectrum pairs with period around 60–80 days from day 100 to 300 (i.e., region surrounded by black dash line in Fig. 2). Relating these positive-negative pairs to the groundwater level variation, we can find that the positive amplitude spectrums are corresponding to the rising of water level while the negative are corresponding to the falling. Based on the relation between spectrogram and physical significance, we then can infer that the groundwater level at Tan-Cian (1-1) and Si-Hu (1) have seasonal periodic cycles with period around 60–80 days from day 100 to 300. The riverstage and precipitation bears similar periodic behaviors but amplitude spectrum of riverstage is twice longer than that to the stream variation, and the wavelet amplitude spectrum of precipitation is twice smaller than that to the stream variation, the effect of precipitation on groundwater fluctuation within the entire alluvial fan thus can be excluded from the groundwater variation data. Moreover, since long-term groundwater level fluctuations at different wells do not exhibit significant difference in their hydrographs, utilizing annual variation likely will not lead to detailed subsurface heterogeneity than utilizing the seasonal scale variation. For this reason, seasonal variation (Julian day 130–200) during 2010 is utilized to characterize subsurface heterogeneity employed by cross-correlation and SLE approaches in this study.

The coherence analysis shows that seasonal and annual variations of groundwater level correlate well with those of stream stage and flow rate, and precipitation. However, because the lag time of groundwater responses to precipitation fluctuation is about twice longer than that to the stream variation, and the wavelet amplitude spectrum of precipitation is twice smaller than that to the stream variation, the effect of precipitation on groundwater fluctuation within the entire alluvial fan thus can be excluded from the groundwater variation data. Moreover, since long-term groundwater level fluctuations at different wells do not exhibit significant difference in their hydrographs, utilizing annual variation likely will not lead to detailed subsurface heterogeneity than utilizing the seasonal scale variation. For this reason, seasonal variation (Julian day 130–200) during 2010 is utilized to characterize subsurface heterogeneity employed by cross-correlation and SLE approaches in this study.

### 4.2. Spatial analysis of groundwater and riverstage data

Maximum cross-correlation values are illustrated in Fig. 5a between the riverstage at Ziqiang station and groundwater levels at all observation wells, during 2010. The cross-correlation contour map indicates two areas where groundwater level is highly correlated with stream stage variation at Zhuoshui River alluvial fan. The first area locates at the north side of the fan and has highest cross-correlation around 0.7. The second, where the maximum cross-correlation is about 0.7, locates at the downstream of the Zhuoshui River. Overall, the spatial distribution of the cross-correlation suggests that groundwater fluctuation in the area locates at the northern of the river and the tail of the fan near the river are highly positive correlated with the riverstage variation at the gauging station. In the apex of the alluvial fan, groundwater fluctuations are always negative or uncorrelated with the river variation. Southeast part of the fan is an uncorrelated or small correlated region.

Fig. 5b is the contour map of time lag of the maximum cross-correlation between groundwater variation at different parts of
the aquifer and the riverstage fluctuation at the gauging station. Lag time is the time elapse that the responses of groundwater level at given location lags behind the stream variations. It generally depends on the distance between the groundwater level observation location and the river as well as the aquifer characteristics through which the pressure perturbation induced by riverstage travels. According to this figure, at the apex of the fan, it will take about 15 days for the aquifer to respond to the riverstage perturbation at Ziqiang Bridge. Distinct patterns exist from the apex to the tail and from north to south. The physical explanations for these correlations are discussed in Section 4.4.

In summary, at apex of the fan, variation of groundwater level is small, not correlated with variation of stream stage, and lags behind the riverstage fluctuation. At the rest of the region, the correlation...
relation between stream stage and groundwater level are relative higher with relative shorter lag time. That is, by examining the spa-
tial cross-correlation and time lag contour maps, we may postulate
that the apex of the fan has its unique subsurface characteristic,
which is significantly different from those at middle and tail of
the fan. That is to say, using the stream induced seasonal ground-
water level variations at different regions we could possibly map
the subsurface characteristics over the alluvial fan.

4.3. Synthetic experiment

To test aforementioned postulation and to assure that the river-
stage tomography analysis using field data will lead to meaningful
results, we create a synthetic, basin-scale heterogeneous aquifer
and simulate its groundwater responses induced by known river-
stage fluctuations. These simulated groundwater and river stage
data sets are error free, and interference of unknown processes
(e.g., pumping events, earthquakes, earth tides, barometric varia-
tions, and boundary effects) are excluded. Moreover, aquifer
heterogeneity distribution is known precisely. Thus, the hypothesis
about the usefulness of the cross-correlation and time lag in terms
of mapping heterogeneity can be assessed. Furthermore, the toler-
ance of the algorithm to the white noise can be evaluated.

4.3.1. Synthetic aquifer

Based on the hydrogeologic map of Zhuoshui River alluvial fan, a
two-dimensional horizontal domain of 80 × 60 square elements is
built. Each element is 1.0 km × 1.0 km. This synthetic aquifer is
divided into three zones, consisting of gravels, sands, and clays. This
general spatial pattern of sediment distribution is to mimic the one
reported by Chang et al. (2015). Afterward, the detailed spatial D
distribution within each zone is generated using a spectral method
random field generator (Gutjahr, 1989; Robin et al., 1993) with the
following statistical characteristics: The mean of $D$ for gravel, sand,
and clay are 7.2 × 10^{11}, 7.2 × 10^{7}, and 7.2 × 10^{3} (m^2/hr), respec-
tively. The variances of ln $D$ (i.e., natural logarithm of $D$) of the cor-
responding materials are 0.3, 1.0, and 2.2. Notice that the variances
of $D$ can be calculated by $D = \exp(\sigma^2) 1$ where $D$ represents
the mean of $D$ while $\sigma^2$ represents the variance of ln $D$. The correlation
scales for the corresponding materials are 10, 25, and 40 (km) for
both x and y directions. These correlation scales are selected to be
approximately half of the width of each material zone. Values and
spatial distribution of $D$ for all the elements in the synthetic aquifer
are shown in Fig. 6. For the synthetic case with noise considered,
white noise with a standard deviation of 0.6 m were superimposed
onto the simulated hydrographs. The average signal-to-noise ratio,
defined as the ratio of observed drawdown to standard deviation
(known) of the noise, is 0.1.

The western and eastern boundaries are constant head bound-
aries to mimic the hydrogeologic setting of Zhoushui River alluvial
fan. The constant head at the eastern boundary is 120 m higher than
that at the west. Head gradient between headwater and coast is used
to mimic the natural regional groundwater flow gradient in the fan.

Fig. 3. (a) Riverstage time series (black line) at Ziqiang Bridge and groundwater time series (blue line with circle) from well Tan-Cian (1-1) as well as wavelet coherence
between the groundwater and the riverstage series. The rise of arrows indicates delay in groundwater response. The rise angle from the horizon is the phase lag with unit in
cycle. The values in the region above the white dash line are uncertain due to the limited length of the time series. (b) is the same as (a) but the groundwater time series is
from well Si-Hu (1) (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.).
A river is placed through the middle of the fan while another river is at the north. Both of the rivers are treated as prescribed time-varying head boundaries rather than flux boundary used in Yeh et al. (2009) since infiltration fluxes of the real world situation are unknown along the river. The rest of the boundaries are no flow boundary because they are either hills that could be considered as watershed divides between two different basins or relative small streams that has little effect on the groundwater fluctuation.

In order to simulate river induced groundwater variation, continuous riverstages along Zhuoshui River and Wu River at different times are generated by interpolation of the riverstage records measured from five stream gauge stations (i.e., four at Zhuoshui River and one at Wu River). For Zhuoshui River, because the flood wave propagating from the apex to tail of fan only takes about 8 h and the distances between gauges are short (only about 10 km), the riverstages between every two stream gauges are obtained simply by linear interpolation. For Wu River, because it is a northern boundary only about 10 km long, the stream stage along the Wu River is simply assumed constant head spatially. These interpolated riverstage temporal and spatial variations are then used as prescribed heads along these rivers in the finite element numerical variable saturated flow model VSAFT2 (Yeh et al., 1993) to simulate groundwater responses.

4.3.2. Cross-Correlation analysis

Fig. 7a displays the result of the cross-correlation analysis, using the synthetic groundwater and riverstage data. It is a contour map of highest cross-correlation between simulated groundwater level variations at different wells and the riverstage fluctuations given at the Zhiqiang Bridge gauging station at downstream of the river. At first glance of the cross-correlation contour map, it apparently captures the general pattern of the reference field (Fig. 6). In other words, clusters of high permeability zones are located at similar areas where cross-correlation values are high. Meanwhile, the locations of the low permeable zones correspond to those of the low cross-correlation values. This result reveals that signals of riverstage fluctuations can propagate far distance away from the river; the signals travelling from the river to individual wells are modified by aquifer heterogeneity. These results thus substantiate the theory of hydraulic tomography for characterizing basin-scale heterogeneity, which uses riverstage fluctuations as the transmitter and wells as receivers of the signals in geophysical survey terminology.

4.3.3. Estimate of D spatial distribution

Following the cross-correlation analysis, the simulated groundwater responses at 65 wells over a period of 70 days are used to conduct the riverstage tomography analysis. Since only riverstage variations are used without knowing the fluxes into the aquifer or hydraulic conductivity values along the river bed, the riverstage tomography can estimate diffusivity (i.e., the ratio of $K$ to $S_s$) only (see Mao et al., 2013a; Yeh et al., 2015b). This analysis is carried out using SLE, with the known boundary and initial conditions and starting with a uniform mean $D$ value for the entire aquifer,
without specifying the spatial distributions of gravel, sand, and clay in the aquifer.

Fig. 7b illustrates that the estimated high $D$ zones (red) occupy the apex of the fan and region around the northern boundary while the relative low $D$ zones (blue) extend throughout the southern part of alluvial fan. These high and low $D$ patterns are generally consistent with those of the reference field (Fig. 6). Noticeably, these patterns are not restricted to the areas closer to the wells or the time varying river boundary where heads were observed and used in the estimation. They also cover areas far away from the wells or near the boundaries of the aquifer. This result indicates that the head at a specific point within an aquifer during the flood event is affected by subsurface hydraulic properties even far away from the observation and near the boundary of the aquifer.

The estimated $D$ values are plotted against the reference $D$ values in Fig. 7c as a scatter plot. Overall, the estimated pattern is consistent with that of the reference field with bias but the estimated values are scattering largely around the true values. The distribution of the residual variances (uncertainty) of the estimated $D$ (not displayed here but has similar pattern with the uncertainty field displayed in Fig. 10b) shows that the residual variances of the estimates increase as the distance to the monitoring well increases. That is, the shorter the distance between the well or the river, the smaller the uncertainty of the estimate, and the longer the distance, the larger the uncertainty of the estimate. The large scattering of the scatter plot thus is likely due to insufficient number of observed groundwater wells. On the other hand, the unknown trends (the mean value of each zone), which inevitably augment the variance of $D$ to be estimated, may also contribute to the large scattering of the estimate.

Fig. 7c also shows that the spatial variance in the reference field is much higher than the spatial variance of the estimated field. Specifically, there are three clusters of data corresponding to the three material types of the reference field. The sand is less biased but not so for clay and gravel. In particular, the $D$ for gravels is underestimated by about two orders of magnitude while for clay is overestimated by about one order.

Based on the above observations, some prior information about the general sand, gravel, and clay zone used as initial starting values of $D$ to riverstage tomography analysis may improve the estimates. The prior information is composed of geometries of gravel, sand, and clay zones, and their corresponding means of the $D$ of the reference field. Fig. 8a and b display the estimate $D$ fields and the associated scatter plots. As illustrated in these figures, the prior geological knowledge is used, the bias and errors of the estimates are significantly reduced. The reduction is reflected in slope and $R^2$ of linear regression line between estimate and reference $D$. Compared this case with that without any prior information, the slope increases from 0.66 to 0.98, indicative of a significant bias reduction. The improvement of the estimation
reveals that the use of prior information allows the final estimations of each zone reflect the true mean in the reference field and reduces the variability of $D$. This can be also attributed to the fact that during our analysis, only riverstage and groundwater level data are used, and no flux data are available to constrain the estimates, as does hydraulic tomography, where pumping rates are known. The roles of prior geological information on the riverstage tomography agree with the finding shown in Tso et al. (2016), Zhao et al. (2016) and Zhao and Illman (2017).

It should be emphasized that although the overall estimate is improved if the prior information is included, there remain areas where $D$ values are over- or under-estimated. Nonetheless, without data that satisfy the necessary conditions for an inverse problem to be well defined, the best an inverse model can do is to obtain an unbiased estimate field (Yeh et al., 2015a,b).

4.4. Application to Zhuoshui river alluvial fan

The next step is to apply riverstage tomography analysis to the field problem, where errors due to measurements, model, and other factors, which are not considered in the model (e.g., effects of unknown pumping, precipitation, and others), are included. That is, we use the interpolated riverstage data and field observed groundwater records at all the observation wells in the upper aquifer to estimate $D$ field of the corresponding aquifer. The model setup is identical to that of the synthetic case.

Fig. 10a and b illustrates the estimated $D$ field by riverstage tomography and the uncertainty of estimated $D$, respectively. As shown in Fig. 10a, the estimated $D$ values decrease from the apex in Fig. 9a and distributed $D$ in Fig. 9b) are similar with those of noise-free cases. The effect of white noise to the estimation of aquifer property is apparently not critical as long as many data points in well hydrographs are used. This is consistent with those findings by (Mao et al., 2013b).
to tail of the fan as well as from the north to the south. By comparing Fig. 10a with Fig. 5a (cross-correlation contour map) and with the lag time contour map (Fig. 5b), we observe that the patterns of the high and low $D$ estimates in Fig. 10a resemble those of the time lags in Fig. 5b more than those in Fig. 5a. Fig. 10b shows that the uncertainty of the estimated $D$ increase as the distance to the monitoring well increases. That is, we have more confidence on the estimates near the river and the monitoring wells.

Overall, the analysis shows that the apex of the fan has its unique subsurface characteristic. This characteristic is significantly different from those at middle and tail of the fan. As observed in Fig. 5, in the apex of the alluvial fan, groundwater fluctuations are always negative or uncorrelated with the river stage variation and lag behind the river stage about half of a month. While at the other region of the fan, the time lags are essentially less than 5 days with positive correlation. Such a long lag of time at the apex of the fan could be attributed to the sediment texture size and depth of the groundwater table. Based on well logs and geologic survey, the apex mainly consists of coarse gravel while the groundwater table is at 30 m depth below ground surface. This coarse-textured vadose zone provides a large storage reservoir for the river water (large porosity), and it not only filters out high frequency signals but also delays the response of water table. These reasons seem to support the relative high $D$ zone estimated by river stage tomography.

Overall, the application of the river stage tomography reveals that the apex region has relative high $D$ values, while the middle area has intermediate $D$ values, and the tail has relative low $D$ values. Such a spatial $D$ pattern agrees with the well logs and geologic survey, which reports that apex mainly consists of gravel and the middle and tail of the fan are consist of sand and silt/clay.

The result of river stage tomography analysis also indicates that the subsurface characteristic at northern alluvial fan differs from the southern part as well. The estimated $D$ are relative larger at north than at south. This finding agrees with Chang et al. (2015)’s conclusion. Chang et al. (2015), integrating the well log

![Fig. 8](image1.png)

![Fig. 9](image2.png)
with electric resistivity survey to investigate this area, found that the northern part of alluvial fan consists of mainly sand with some silt/clay layer along the coast while the southern fan is mainly composed of silt/clay. Such distributions of sediments have been attributed to difference in sediment sources. That is, the southern alluvial fan is mainly deposited by the Beigang River, while the northern fan is deposited by Zhuoshui River. Specifically, Zhuoshui River probably mainly flowed through the northern part of the fan in the ancient time. This river is originated from Central Mountain Range, has steeper riverbed gradient and thus great sediment transport capacity. It transports not only sand but also gravel and cobbles, even boulders during large flood events. On the other hand, Beigang River originates from Douliu Hills, which is a smaller hill and has smaller hydraulic gradient. It carries only sediment size smaller than sand (Water Resources Agency, 2014).

Notice that a highly parameterized conceptual model is used in this riverstage tomography analysis. This implies that the $D$ parameter in each element of this model is assumed locally isotropic. In other words, we assume that the element-scale anisotropy is not as significant as the spatial variability of $D$ values of each element over the entire alluvial fan.

Finally, the omission of irrigation pumping, precipitation, and other processes and the assumption of a two-dimensional aquifer in the riverstage tomography analysis likely introduce errors in the estimates of true hydraulic parameters in the Zhuoshui River alluvial fan. Our estimates, nevertheless, reflect general heterogeneity trends in the alluvium fan, which are consistent with geology.

5. Conclusion

Using wavelet analysis, we find that long-term variations in riverstage are correlated well with groundwater level variation over large areas in the alluvium fan under investigation. The cross-correlation analysis of these long-term data yield contour maps of maximum cross-correlation values and time lags. Spatial patterns of these contour maps are similar to patterns of geologic deposits over the alluvium fan. This finding is further substantiated by numerical experiments. That is, groundwater level variations induced by riverstage variations in a synthetic aquifer with known hydraulic property distribution are simulated. Results of the cross-correlation analysis of these simulated data sets show that the spatial patterns of cross-correlation are consistent with the known hydraulic property distribution. This finding implicitly affirms the feasibility of riverstage tomography analysis using SLE, which is built upon the cross-correlation. The synthetic experiments also show that when the geologic zones knowledge is included as prior information for the riverstage tomography analysis, the overall estimate improves. In other words, the prior information about the mean value of each zone reduces the variability of the parameters to be estimated.

Applications of the riverstage tomography to Zhuoshui River alluvial fan show that the apex of the alluvial fan is a region with relative high $D$, which is likely the main recharge area of the aquifers. $D$ values gradually decrease toward the shoreline of the fan. In addition, $D$ at northern alluvial fan is larger than $D$ at southern. These findings are in agreement with previous geological survey but the riverstage tomography quantifies the $D$ values.

While many assumptions are invoked in this analysis, the results certainly encourage further investigations of the concept of riverstage tomography for characterizing large-scale groundwater basins.
